Abstract: The degradation of lignocellulose in biogas processes has been focused on the inoculant
  microorganisms involved, with a view to gaining a deeper understanding and improving lignocel-
  lulose degradation. The maximum volumetric biogas yield (12.17 L/L) was achieved with inocula-
  m used in experiment “B” containing 400 g of digestate from the bioreactor along with 400 g of rumen
  fluid. The highest concentration of methane in biogas was obtained from the same inoculum com-
  position (63.2 ± 1.5%). The second largest volumetric yield of 8.41 ± 0.45 L/L biogas was achieved in
  experiment “C,” where digestate were used as the main inoculum. Accordingly, in this case the
  volumetric yield of biogas was 8.41 ± 0.45 L/L. The composition of rumen fluid and digestate in-
  creased biogas production from the same amount of alfalfa leaves 30.9%.

Keywords: anaerobic inoculum; bacteria; feedstock; anaerobic digestion; alfalfa; biomass; biomethane

1. Introduction

  Alfalfa leaves (AL) is an excellent feedstock as biogas production material for anaer-
  obic co-digestion (AD) because of its organic solids content of more than 20%. However, a high
  concentration of fibers and lignocellulose, material ability to layering makes this
  feedstock problematic to digest in CSTR bioreactors. Lignocellulosic biomass has a huge
  potential to be used as feedstock for the sustainable production of fuels and chemicals
  through fermentation. Today, plant substrates, also entitled lignocellulosic biomass, are
  seen as one of the most promising materials to replace fossil energy resources in the pro-
  duction of fuels and chemicals with reduced GHGs emissions [1].

  The influence of inoculum used for anaerobic lignocellulosic biomass treatment in
  every specific case varies. In cellulolytic rumen bacteria, highly active cellulosytic and
  hemicellulolytic enzymes are combined in extracellular multienzyme complexes, cellulo-
  somes [2]. Recent research related to the degradation of lignocellulose in biogas processes
  has had a strong focus on the microorganisms involved, with the aim of further under-
  standing and improving degradation. These studies have e.g., evaluated the whole bacte-
  rial and archaea community by analyzing the 16 rRNA genes [3]. Improving the perfor-
  mance of the microbial strains for an efficient conversion of sugars from complex sub-
  strates (hydrolysates produced from lignocellulosic biomass) is an important question to
  be solved to support the large-scale implementation of these bioprocesses. Researchers
  investigated the degradation of straw and cellulose during batch cultivation using mate-
  rial from different full-scale biogas plants as the inoculum source [4]. The results showed
  similar biogas yields but differences in the degradation rate, as well as a correlation be-
tween degradation rate and the composition of the cellulose-degrading community. Employing a combination of two or more microbial species for bioprocessing biomass into biogas remains an underrated strategy to increase processing efficiency. Revolutionizing biotechnological biomass usage, a cutting-edge approach involves synergizing multiple microbial species for bioprocessing may enhance overall process efficiency. This co-cultivation approach can potentially alleviate some of the problems associated to the lignocellulose biomass use. The general idea of this concept is to take advantage of the specialized ability of two or more organisms and create a synergistic effect. Since multiple strains are used in a single process, a broader variation in beneficial characteristics can be selected. Optimization of a co-cultivation process could then be performed by selecting the right strains to be combined, instead of engineering one do-it-all strain [2].

The addition of rumen fluid to the anaerobic digestion process can significantly enhance biogas production by providing a diverse range of microorganisms that possess the necessary enzymatic activity to break down complex lignocellulosic materials. The optimal range of rumen fluid addition varies depending on the type of feedstock and operational conditions of the biogas plant, with the ideal range being between 25–50%. However, it is important to carefully monitor the process and avoid overloading the system with rumen fluid, as this can lead to unwanted process disruptions [5].

The aim of the work was to investigate the influence of rumen anaerobic bacteria inoculum on biogas yield and quality from alfalfa biomass.

2. Materials and Methods

The influence of dairy rumen fluid inoculum selected for anaerobic treatment of the organic fraction of alfalfa leaves was studied in this work. Dairy rumen fluid was taken from the dairy farm in southwestern Lithuania. The rumen fluid was packaged in an air-tight container of 15 L and stored at 37.0 ± 0.2 °C to be protected from environmental influences until the start of the experiment. The transportation period from the collection of rumen fluid to the start of the experiment took 2 h. Prior to the commencement of the experiment, the dairy rumen fluid was filtered through a 0.5 mm stainless steel mesh.

The chemical analysis of the feedstock was carried out on alfalfa biomass composition content. Dry organic matter (VS) was performed according to LST EN 13039:2012, using the gravimetric method.

A single-load biogas yield experiment was carried out on a biochemical methane potential test bench (BMP). The mesophilic temperature was maintained at 37.0 ± 0.2 °C during the experiment. To determine the potential biogas yield and production from alfalfa biomass, four separate BMP experiments were conducted with triplicate samples for each experiment set. As the feedstock composition in A, B, C sets, the same amount of alfalfa biomass was added—16 g. Reactor set “A” was inoculated with 800 g of rumen fluid (proportion 100%/0%), Reactor set “B” was inoculated with 400 g rumen fluid and 400 g digestate from laboratory bioreactor using wheat straw as a feedstock (proportion 50%/50%), Reactor set “C” was loaded with 800 g digestate directly from the same bioreactor as mentioned in Reactor “B” (proportion 0%/100%). To evaluate residual methanogenic activity inoculum BMP Reactor “D” was started without any alfalfa addition and it served as a negative control sample. The experiments were performed in triplicates to ensure experimental data reliability.
Biogas volume from each bioreactor was monitored daily and the concentration of methane (CH$_4$), carbon dioxide (CO$_2$) and hydrogen sulphide (H$_2$S) were monitored after the 35 days experiment. The amount of gas formed was registered with RITTER Milligascounters (2). The 20-L volume Tedlar PVF gas sampling bag (3) was used for biogas collection. The collected biogas was analyzed with an Awite Bioenergie GmbH AwiFlex (Germany) biogas analyzer (4).

3. Results and Discussion

The measured pH of digestate and rumen fluid inoculants was respectively 7.3 and 6.1. The normal pH of dairy cow rumen fluid is typically between 6.0 and 7.0. However, it can fluctuate depending on the cow’s diet and feeding schedule [6]. The pH in the digestate typically varies from 6.5 to 8.2, [7] with optimal values for anaerobic digestion producing methane of 6.8–7.2 [8].

The main feedstock for experiment was crushed alfalfa leaves biomass, is evenly dry and homogeneous at total solids (TS) content of 64.3% and vs. concentration of 91.9%. The total and volatile solids content of alfalfa leaves can vary depending on factors such as the stage of growth, weather conditions, and location.

In the present study, the total solids and volatile solids tests were also conducted for both the digestate and rumen fluid. The digestate and rumen fluid inoculants had low total solids concentrations in this experiment, with a respective concentration of 4% and 1.8%. The volatile solids content in these inoculants was observed to be high, with respective values of 98.2% and 97.4%. It is important to note that volatile and total solids experiments were conducted for sieved digestate and rumen fluid.

The results of the BMP experiment indicated that the highest volumetric biogas yield of 12.17 ± 0.62 L/L was achieved in test B, where a combination of rumen fluid and digestate was used as an inoculum for alfalfa leaves. The second highest volumetric biogas yield of 8.41 ± 0.45 L/L was obtained in test C, where bioreactor digestate were used as inoculum for alfalfa leaves. These findings suggest that the increase in biogas yield was due to the presence of highly active cellulolytic and hemicellulolytic enzymes, which are combined in extracellular multienzyme complexes known as cellulosomes [9].

Volumetric biogas yield from A and D experiments were the lowest. The least gained biogas was from experiment “A” with rumen fluid and alfalfa biomass it was only 1.14 L/L ± 0.17 L/L. The volume of gained biogas from experiment “A” was too low to analyze its composition. In experiment “A”, liquid rumen fluid, used as an inoculum was utilized with alfalfa addition to assess its methanogenic activity. The least volumetric yield of biogas came from digestate (0.35 ± 0.08 L/L) as it did not contain additional alfalfa leaves biomass.

The concentration of methane in the biogas was also dependent on the inoculum used for the research. It’s necessary to mention that only B and C experiments gained enough biogas to analyze it with Awite biogas analyzer. The highest concentration of methane was gained from experiment B (63.2 ± 1.5%). Biogas gained from digestate (experiment C)
had a lower concentration of methane, at 54.6 ± 1.1%). This finding fulfills the conclusions from the experiment conducted by Zheng et al. 2019, which demonstrated that a ratio of 1:5 of rumen microorganisms to biogas slurry yielded high methane production and content, thereby establishing it as the optimal ratio [10].

The biomethane yield from alfalfa volatile solids using obtained in experiment B and experiment C was respectively 598 ± 8.3 and 357 ± 12.4 L/kg. The employment of digestate and ruminant inoculum resulted in a 32% increase in biomethane yield, in contrast to the C sample, where pure digestate was used as an inoculum. The experiment B yielded a biomethane yield of 668 ± 12.2 L/kg from the total solids of alfalfa, whereas the experiment C produced a biomethane yield of 462 ± 18.3 L/kg.

Hakl et al., 2012 performed experimental research on alfalfa biomethane yield. In their experiment approximately from 250 to 390 L CH₄/kg vs. of lucerne forage was obtained [11]. Comparison of research results suggest that optimizing the conditions of alfalfa digestion, such as feedstock characteristics, inoculum type, and operating conditions, will lead to improved biomethane yields.

Experimental results of the research complements the (Nagler et al., 2019) research that the inclusion of rumen liquid enhances the degradation of complex lignocellulosic compounds by providing a diverse range of cellulytic and hemicellulolytic microorganisms [12]. This leads to an increase in biogas production and improved process stability. The authors suggest that the addition of rumen liquid could be a simple and effective strategy to enhance the performance of lignocellulose-degrading biogas plants.

4. Conclusions

Through a series of laboratory BMP experiments, the effect of using rumen fluid dairy cows as an inoculum on biogas production rate was studied. Experiment B, which inoculated rumen fluid and digestate, yielded the maximum volumetric biogas yield of 12.17 ± 0.62 L/L. The second largest volumetric yield of biogas was observed in experiment C, which used only digestate as inoculum, with a yield of 8.41 ± 0.45 L/L. The combination of rumen fluid and digestate in the inoculum for experiment B resulted in a 30.9% increase in biogas production from the same quantity of alfalfa biomass. Dairy rumen fluid inoculated BMP experiment resulted a methane concentration of 63.2 ± 1.5%, while digestate inoculated experiment yielded a slightly lower concentration of methane at 54.6 ± 1.1%. Therefore, the use of rumen fluid in combination with digestate increased the methane concentration by approximately 8.6% (63.2–54.6) in methane content in biogas. The biomethane yield from alfalfa volatile solids obtained in experiment B and experiment C was respectively 598 ± 8.3 and 357 ± 12.4 L/kg. The employment of digestate and ruminant inoculum resulted in a 32% increase in biomethane yield, compared to the C sample, where pure digestate was used as an inoculum. These findings suggest that utilizing a mixture of rumen fluid and digestate as the inoculum can significantly enhance the biogas production from alfalfa biomass.
