**Biocontrol of plant pathogens**

Biocontrol: use of biocontrol agents or BCAs (fungi, bacteria, yeasts, or viruses) that may suppress plant pathogens via competition for nutrients or space, antibiosis, parasitism, and induced host plant resistance.

- A sustainable method of disease management;
- A viable way to reduce the application of chemicals in agriculture;
- The global reliance on BCA use remains relatively insignificant.

Reason for poor and/or inconsistent efficacy in the field

- BCAs are often used in a similar manner as fungicides;

- Factors influencing fitness and efficacy of biocontrol microorganisms are not fully known;

- The complex relationships between BCAs and the environment remain difficult to predict and manage;

Mathematical models can help understanding complex and dynamic interactions among a target pathogen, host plants, and the BCA population in a changing environment.
A model able to predict the likelihood of the successful control of foliar diseases by a single BCA as a function of the biocontrol mechanisms involved.

Host–pathogen dynamics are coupled with pathogen–BCA dynamics through four biocontrol mechanisms:
1. mycoparasitism;
2. competition;
3. antibiosis;
4. induced plant resistance.

Model development

The model proposed by Jeger et al. (2009) was enlarged by including:

- The effects of environmental conditions on the interactions between the pathogen and BCA;

- The dynamics of host growth and senescence.

The model is generic: can be operated for fungal pathogens and for BCAs with different mechanisms of action (MOA).
The model was developed by using the software STELLA®

State variables represent plant tissue categories.

Host processes (growth and senescence) are also represented.

IECPS 2020
The pathogen-BCA dynamics on plant tissue according to mechanisms of action (MOA)

- **Resistant**
- **Healthy & BCA colonized**
- **Infected & BCA colonized**
- **Removed & BCA colonized**

Diagram showing the dynamics with various symbols and labels.
The pathogen-BCA dynamics on plant tissue according to mechanisms of action (MOA)

1. mycoparasitism;
2. competition;
3. antibiosis;
4. induced plant resistance.
Pathogen infection rate is influenced by temperature and relative humidity

\[ b_t = (\alpha \times T_{eqt}^\beta \times (1 - T_{eqt}))^\theta \times \exp (-\varphi \times \exp (-\gamma \times M_{Dt})) \]

BCA growth rate is influenced by temperature and moisture

\[ GRO = (\gamma \times T_{eqt}^\zeta \times (1 - T_{eqt}))^\nu / \left( 1 + \exp \left( -\psi \times \frac{R_{Ht}}{100} \right) \right) \]
Model parametrization

The model was parametrized for the Botrytis cinerea–grapevine pathosystem.

The model was parametrized for the biocontrol of BBR in grapevine clusters between “veraison” (GS83) and “berries ripe for harvest” (GS89).

- Temperature and moisture requirements for B. cinerea to cause infection;
- MoA of the BCA;
- Timing of BCA application with respect to the pathogen;
- Temperature and moisture requirements for BCA to grow and survive.
The model was used to study the effect of the following sources of variation on BBR development:

- MOA of the BCA: mainly competition and mainly mycoparasitism;
- BCA application time (as preventative or curative);
- BCA strain: 3 ranges of temperatures combined with 3 moisture requirements for BCA growth;
- BCA survival capability: low, medium, and high.

... 981 model runs (1 NT + 108 BCA combinations) under 9 scenarios, reflecting three climate types: cold and wet, mild and semi-arid, and warm and dry.
Total tissue occupied by the pathogen as affected by MOA, application time, and climate type.
The final values of AUDPC simulated for each of the 981 runs of the model were used to calculate the efficacy (E) of each BCA combination (T) in relation to the untreated control (NT):

\[ E = \frac{\text{NT} - T}{\text{NT}}. \]

BCA efficacy against Botrytis bunch rot in ripening grapevine clusters, as affected by MOA; responses of 9 BCA strains to temperature; BCA survival capability; and climate.
BCA efficacy against BBR in ripening grapevine clusters averaged across nine BCA strains and as affected by BCA survival capability and climate type: (A) cold and wet, (B) mild and semi-arid, and (C) warm and dry.
BCA efficacy against Botrytis bunch rot in ripening grapevine clusters of nine BCA strains

BCA response (growth and survival) to environmental conditions plays a prevalent role in their efficacy, accounting for > 90% of simulation variability.
Conclusions

✓ Importance of considering the environmental response of the BCA during its selection;

✓ Importance of considering the BCA survival capability during both selection and formulation;

✓ Importance of considering the weather conditions and forecasts at the time of BCA application in the field.
